```

We often find ourselves in this situation. We know each file has the same structure, and we would like to use them all at once.

Loops?

How to read them all in?

One traditional way, which we could do in R, is to write an explicit *loop* that iterated over a vector of filenames, read each file, and then joined the results together in a tall rectangle.

Loops?

You may have noticed we have not written any loops, however.

While loops are still lurking there underneath the surface, what we will do instead is to take advantage of the combination of vectors and functions and *map* one to the other in order to generate results.

Speaking loosely, think of map () as a way of iterating without writing loops. You start with a vector of things. You feed it one thing at a time to some function. The function does whatever it does. You get back output that is the same length as your input, and of a specific type.

Mapping is just a kind of iteration

The purrr package provides a big family of mapping functions. One reason there are a lot of them is that purrr, like the rest of the tidyverse, is picky about data types.

Mapping is just a kind of iteration

The purrr package provides a big family of mapping functions. One reason there are a lot of them is that purrr, like the rest of the tidyverse, is picky about data types.

So in addition to the basic map(), which always returns a *list*, we also have map_chr(), map_int(), map_dbl(), map_lgl() and others. They always return the data type indicated by their suffix, or die trying.

The simplest cases are not that different from the vectorized arithmetic we're already familiar with.

```
a <- c(1:10)
b <- 1
# You know what R will do here
a + b
## [1] 2 3 4 5 6 7 8 9 10 11</pre>
```

The simplest cases are not that different from the vectorized arithmetic we're already familiar with.

```
a <- c(1:10)
b <- 1
# You know what R will do here
a + b
## [1] 2 3 4 5 6 7 8 9 10 11
```

R's vectorized rules add b to every element of a. In a sense, the + operation can be thought of as a function that takes each element of a and does something with it. In this case "add b".

We can make this explicit by writing a function:

```
add_b <- function(x) {
  b <- 1
  x + b # for any x
}</pre>
```

Now:

```
add_b(x = a)
## [1] 2 3 4 5 6 7 8 9 10 11
```

Again, R's vectorized approach means it automatically adds b to every element of the x we give it.

```
add_b(x = 10)

## [1] 11

add_b(x = c(1, 99, 1000))

## [1] 2 100 1001
```

Some operations can't directly be vectorized in this way, which is why we need to manually iterate, or will want to write loops.

That's tedious to write! Computers are supposed to allow us to avoid that sort of thing.

4060

1

142

12

1626

So how would we iterate this? What we want is to apply the n_distinct() function to each column of gapminder, but in a way that still allows us to use pipelines and so on.

```
library(gapminder)
gapminder %>%
  summarize(n distinct(country),
             n distinct(continent),
             n distinct(year),
             n distinct(lifeExp),
             n distinct(population))
## # A tibble: 1 × 5
     `n_distinct(country)` `n_distinct(continen...` `n_distinct(ye...` `n_distinct(li...`
##
                      <int>
                                              <int>
                                                                <int>
                                                                                  <int>
## 1
                        142
                                                                   12
                                                                                   1626
## # ... with 1 more variable: `n distinct(population)` <int>
```

Using **n_distinct()** in this context is an idea I got from Rebecca Barter's discussion of purrr.

You'd use **across()**, like this:

```
gapminder %>%
   summarize(across(everything(), n_distinct))

## # A tibble: 1 × 6

## country continent year lifeExp pop gdpPercap

## <int> <int> <int> <int> <int> <int> </104</pre>
## 1 142 5 12 1626 1704 1704
```

But you could also do this ...

```
map(gapminder, n_distinct)
## $country
## [1] 142
## $continent
## [1] 5
## $year
## [1] 12
## $lifeExp
## [1] 1626
## $pop
## [1] 1704
## $gdpPercap
## [1] 1704
```

Read it as "Feed each column of gapminder to the n_distinct() function.

(This is pretty much what across() is doing more nicely.)

Or, in pipeline form:

```
gapminder %>%
  map(n_distinct)
## $country
## [1] 142
## $continent
## [1] 5
##
## $year
## [1] 12
## $lifeExp
## [1] 1626
## $pop
## [1] 1704
## $gdpPercap
## [1] 1704
```

You can see we are getting a *list* back.

Or, in pipeline form:

```
result <- gapminder %>%
    map(n_distinct)

class(result)

## [1] "list"

result$continent

## [1] 5

result[[2]]

## [1] 5
```

But we know n_distinct() should always return an integer. So we use map_int() instead of the generic map().

```
gapminder %>%
  map_int(n_distinct)

## country continent year lifeExp pop gdpPercap
## 142 5 12 1626 1704 1704
```

The thing about the map () family is that they can deal with all kinds of input types and output types.

Get a vector of filenames

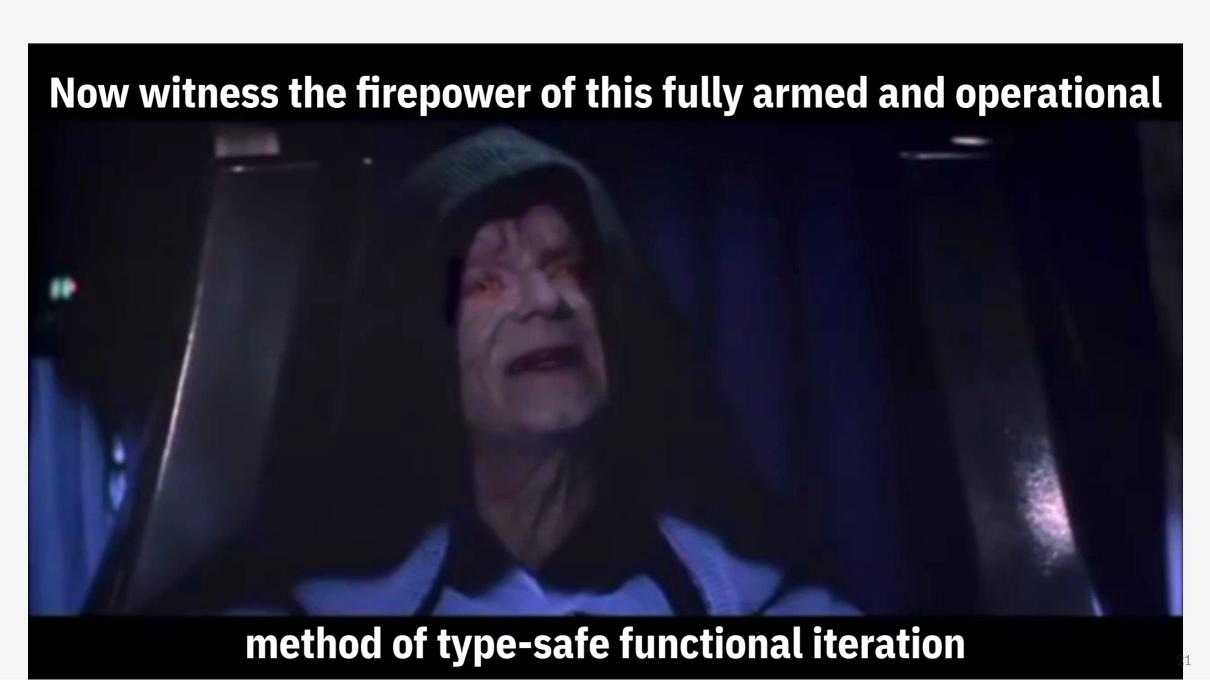

```
filenames <- dir(path = here("data", "congress"),
                 pattern = "*.csv",
                 full.names = TRUE)
filenames[1:15] # Just displaying the first 15, to save slide space
   [1] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/01 79 congress.csv"
   [2] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/02 80 congress.csv"
   [3] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/03 81 congress.csv"
   [4] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/04 82 congress.csv"
   [5] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/05 83 congress.csv"
   [6] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/06 84 congress.csv"
   [7] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/07 85 congress.csv"
   [8] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/08 86 congress.csv"
   [9] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/09 87 congress.csv"
  [10] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/10 88 congress.csv"
  [11] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/11 89 congress.csv"
  [12] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/12 90 congress.csv"
```

[13] "/Users/kjhealy/Documents/courses/data_wrangling/data/congress/13_91_congress.csv"
[14] "/Users/kjhealy/Documents/courses/data_wrangling/data/congress/14_92_congress.csv"
[15] "/Users/kjhealy/Documents/courses/data wrangling/data/congress/15 93 congress.csv"

And feed it to read_csv()

... using the variant of map () that returns data frames and tibbles.

```
df <- filenames %>%
  map dfr(read csv, .id = "congress") %>%
   janitor::clean names()
df
## # A tibble: 20,580 × 26
      congress last first middle suffix nickname born death sex
                                                                         position party

We'll use the lubridate package to sort these out.

Lubridate has a wide range of functions to handle dates, times, and durations.

Cleaning up congress

```
library(lubridate)
 date recodes <- c("born", "death", "start", "end")</pre>
df <- df %>%
    mutate(across(any_of(date_recodes), mdy),
            congress = as.double(congress) + 78)
df

```

We're going to join these tables

We will use **left_join()** which is what you want most of the time when you are looking to merge a smaller table with additional information into a larger main one.

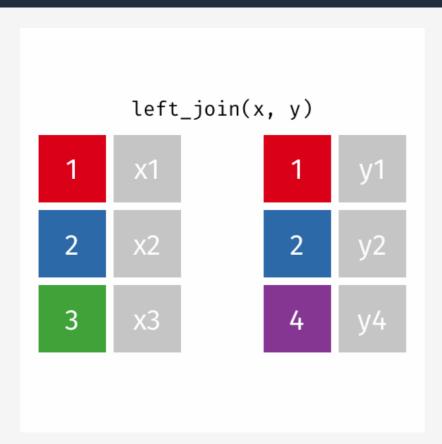

```
df <- left join(df, sessions) %>%
  relocate(start year:end year, .after = congress)
## Joining, by = "congress"
df
## # A tibble: 20,580 × 28
     congress start_year end_year
                                   last first middle suffix nickname born
                                    <chr> <chr> <chr> <chr> <chr>
        <dbl> <date>

Table joins

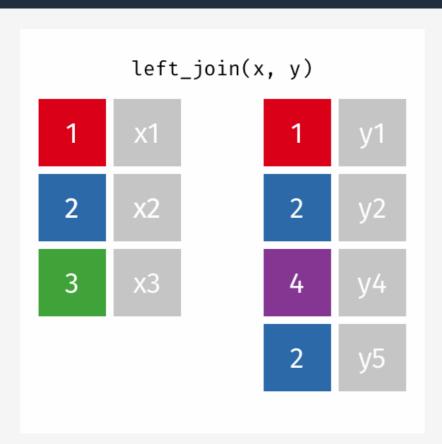

^{*}Spiffy Join Animatations courtesy Garrick Aden-Buie

Left join, left_join()

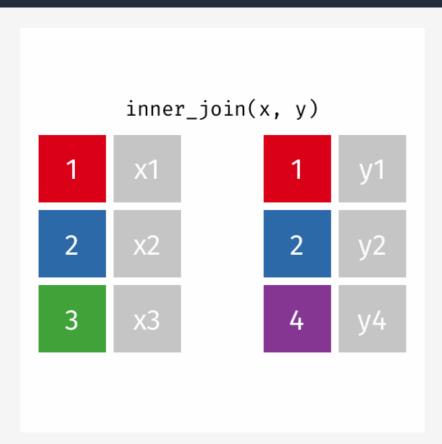

All rows from x, and all columns from x and y. Rows in x with no match in y will have NA values in the new columns.

Left join (contd), left_join()

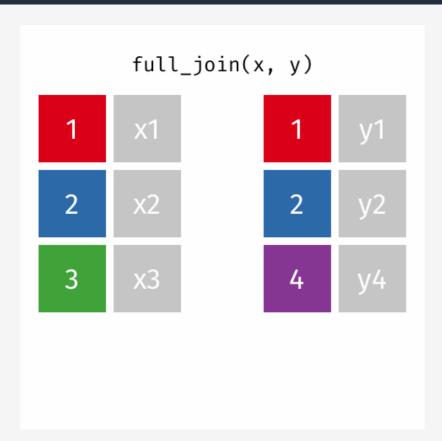

If there are multiple matches between x and y, all combinations of the matches are returned.

Inner join, inner_join()

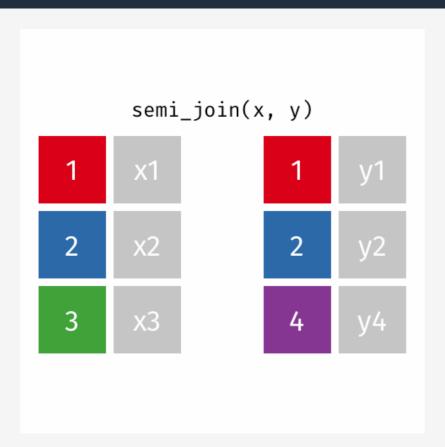

All rows from x where there are matching values in y, and all columns from x and y.

Full join, full_join()

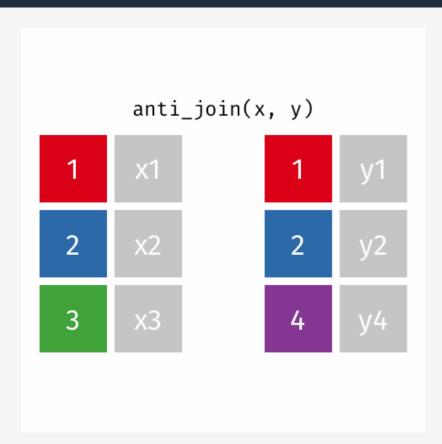

All rows and all columns from both x and y. Where there are not matching values, returns NA for the one missing.

Semi join, semi_join()

All rows from x where there are matching values in y, keeping just columns from x.

Antijoin, anti_join()

All rows from x where there are not matching values in y, keeping just columns from x.

Left join, left_join()

Most of the time you will be looking to make a left_join()

Missing Data

The result of almost any operation involving a missing/unknown value will be missing/unknown.

2 B ## 3 C

4 D

NA

34

The result of almost any operation involving a missing/unknown value will be missing/unknown.

```
# OK
df %>%
filter(age == 25)

## # A tibble: 1 × 2
## subject age
## <chr> <dbl>
## 1 B 25
```

The result of almost any operation involving a missing/unknown value will be missing/unknown.

```
# OK
df %>%
  filter(age == 25)
## # A tibble: 1 × 2
## subject age
## <chr> <dbl>
## 1 B
# Nope
df %>%
  filter(age == NA)
## # A tibble: 0 × 2
## # ... with 2 variables: subject <chr>, age <dbl>
# E.g.
23 == NA
## [1] NA
```

Always use is. na() instead

```
# Yes
df %>%
  filter(is.na(age))

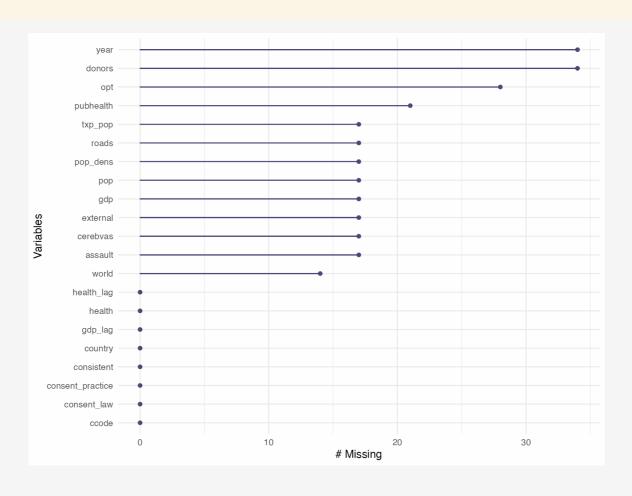

## # A tibble: 1 × 2
## subject age
## <chr> <dbl>
## 1 C NA
```

```
library(naniar)
library(visdat)
```

## # ... with 1,754 more rows
```

Now we've reconstructed the individual-level observations.

Models

This is not a statistics seminar!

I'll just give you an example of the sort of thing that many other modeling packages implement for all kinds of modeling techniques.

Again, the principle is tidy incorporation of models and their output.

We can't *do* anything with this, programatically.

```
